KEYWORDS: Genetic algorithm, Genetic Programming, Decision tree, LISP

ABSTRACT

Genetic algorithm and Genetic programming have been applied in a variety of settings. This paper describes the application of the recently developed "Genetic Programming" paradigm to the problem of hierarchical Classification Systems formulation and induction of decision tree.

1. INTRODUCTION AND OVERVIEW

This paper describes the recently developed "genetic programming" paradigm which genetically breeds populations of computer programs in LISP to solve problems. In genetic programming, the individuals in the population are hierarchical compositions of functions and arguments of various sizes and shapes.

2. BACKGROUND ON GENETIC ALGORITHMS

Genetic Algorithms (GA) is a searching technique used in computing to find true/approximate solutions to optimization and search problem. Genetic Algorithm are a particular class of evolutionary algorithm that use techniques inspired by evolutionary biology such as inheritance, mutation, selection and crossover. GAs has been widely studied, experimented and applied in many fields in engineering world.

2.1 Who can benefit from GA

Nearly everyone can gain benefits from GAs. GAs are useful and efficient when

- The search space is large, complex and poorly understood.
- No mathematical analysis is available
- Traditional search method fails.

2.2 Pseudo-Code Algorithm

1. Choose initial population.
2. Evaluate the fitness of each individual to reproduce.
3. Repeat
a. Select best-ranking individuals to reproduce.
b. Breed new generation through crossover and mutation (genetic operations) and give birth to offspring.

4. Until termination condition.

The common termination conditions are:

a. A solution is found that satisfies minimum criteria.
b. Fixed number of generation reached.
c. Allocated budget (computation time/money) reached.
d. Highest ranking solutions fitness is reached.

3. BACKGROUND ON GENETIC PROGRAMMING PARADIGM

Genetic programming is a branch of genetic algorithm. The main difference between genetic programming and genetic algorithm is the representation of the solution. Genetic programming creates computer programs in LISP or scheme computer languages as the solution. Genetic algorithms create a string of numbers that represent the solution. Entire computer programs can be genetically bred to solve problems in a variety of different areas of artificial intelligence, machine learning, and symbolic processing (Koza 1989, 1990a, 1990b). This new genetic algorithm paradigm has been successfully applied to example problems in several different areas, including (1) machine learning of functions, (2) planning, (3) automatic programming, (4) sequence induction, (5) pattern recognition, (6) symbolic "data to function" regression, symbolic "data to function" integration, and symbolic "data to function" differentiation, (7) symbolic solution to functional equations (including differential equations with initial conditions, integral equations, and general functional equations), (8) empirical discovery, (9) simultaneous architectural design and training of neural networks, and (10) game-playing (e.g. finding a minimax strategy for a differential pursuer-evader game and finding a minimax strategy for a discrete game represented by a game tree in extensive form).

In this recently developed "genetic programming" paradigm, the individuals in the population are compositions of functions and terminals appropriate to the particular problem domain. The set of functions used typically includes arithmetic operations, mathematical functions, conditional logical operations, and domain-specific functions. Each function in the function set must be well defined for any element in the range of every other function in the set. The set of terminals used typically includes inputs (sensors) appropriate to the problem domain and various constants. The search space is the hyperspace of all possible compositions of functions that can be recursively composed of the available functions and terminals. The symbolic expressions (S-expressions) of the LISP programming language are an especially convenient way to create and manipulate the compositions of functions and terminals described above.

The basic genetic operations for the genetic programming paradigm are fitness proportionate reproduction and crossover (recombination). Fitness proportionate reproduction is the basic engine of Darwinian reproduction and survival of the fittest and operates for genetic programming paradigms in the same way as it does for conventional genetic algorithms. The crossover operation for genetic programming paradigms is a sexual operation that operates on two parental LISP S-expressions and produces two offspring S-expressions using parts of each parent. In particular, the crossover operation creates new offspring S-expressions by exchanging sub-lists (sub-trees) between the two parents. Because entire sub-lists are swapped, this genetic crossover (recombination) operation produces syntactically and
semantically valid LISP S-expressions as offspring regardless of which point is selected in either parent. For example, consider the following two parental LISP S-expressions:

\[(\text{OR} \ (\text{NOT} \ D1) \ (\text{AND} \ D0 \ D1))\]
\[(\text{OR} \ (\text{OR} \ D1 \ (\text{NOT} \ D0)) \ (\text{AND} \ (\text{NOT} \ D0) \ (\text{NOT} \ D1) \ (\text{AND} \ D0 \ D1))).\]

Suppose that the second point of the first parent (i.e. the NOT function) is randomly selected as the crossover point of the first parent and that the sixth point of the second parent (i.e. the AND function) is randomly selected as the crossover point of the second parent. The two offspring resulting from crossover are shown below:

\[(\text{OR} \ (\text{OR} \ D1 \ (\text{NOT} \ D0)) \ (\text{NOT} \ D1))\]
\[(\text{OR} \ (\text{AND} \ (\text{NOT} \ D0) \ (\text{NOT} \ D1)) \ (\text{AND} \ D0 \ D1))).\]

4. **HIERARCHICAL CLASSIFICATION SYSTEM FORMATION**

Quinlan (1986) initiated development of a particularly effective family of hierarchical classification systems for inducing a decision tree from a limited number of training case examples. In ID3 (and various other systems of the ID3 family), the goal is to partition a universe of objects into classes. Each object in the universe is described in terms of various attributes. The system is first presented with a set of training case examples which consist of the attributes of a particular object and the class to which it belongs. The system then generates a decision tree which hopefully can then be used to classify a new object correctly into a class using the attributes of the new object. The external points (leaves) of the decision tree are the eventual class names. The internal points of the decision tree are attribute-based tests which have one branch emanating from the decision point for each possible outcome of the test. The induction of such decision trees for classifying objects can be approached by genetically breeding LISP S-expressions for performing this task. In particular, the set of terminals is the set of class names. The set of functions is the set of attribute-based tests. Note that this set of attribute-based tests are always assumed to be given and available for solving induction problems via decision trees of the ID3 family. Notice that ID3 is similar to the genetic programming paradigm in that the set of functions is given. Each function has as many arguments as there are possible outcomes of that particular test. When a particular object is presented to the LISP S-expression (i.e. the decision tree), each function in the S-expression tests one attribute of the object and returns the particular one of its arguments designated by the outcome of the test. If the designated argument is an terminal, the function returns the class name. When the S-expression is fully evaluated in LISP’s usual left-oriented depth-first way, the S-expression as a whole thus returns a class name. That is, the S-expression is a decision tree that classifies the new object into one of the classes.

To demonstrate the technique of genetically inducing a decision tree, we apply this approach to the small training set of 14 objects presented in Quinlan (1986). In Quinlan’s problem, each object has four attributes and belongs to one of two classes (“positive” or “negative”). The attribute of “temperature”, for example, can assume the possible values hot, mild, or cool. Humidity can assume the values of high or normal. Outlook can assume values of sunny, overcast, or rain. Windy can assume values of true or false. The decision tree presented by Quinlan as the solution for this problem is shown below:
If, for example, the OUTLOOK of a particular object is sunny and the HUMIDITY is high, then that object is classified into class 0 (negative).

In order to genetically induce the decision tree, each of the four attributes in this problem is converted into a function. For example, the function “temperature” operates in such a way that, if the current object has a temperature of “mild,” the function returns its second argument as its return value. The other attributes in this problem, namely “humidity”, “outlook”, and “windy”, are similarly converted to functions. The function set for this problem is therefore F = {TEMP, HUM, OUT, WIND} with 3, 2, 3, and 2 arguments, respectively. The set of terminals for this problem is T = {0, 1} since there are two classes. A population size of 300 was used.

In one run, the LISP S-expression (OUT (WIND 1 0) (WIND 1 1) (HUM 0 1)) emerged on the 8th generation with a maximal fitness value of 14 (i.e. it correctly classified all 14 training cases). Since (WIND 1 1) is equivalent to just the constant atom 1, this S-expression is equivalent to the decision tree presented in Quinlan (1986) using ID3.
